## ABSTRACT

This paper explores the relationship between macroeconomic conditions and urban income distribution in Colombia. The results show that unemployment and inflation have significant regressive effects. Manufacturing output growth is clearly progressive, as well as improved conditions in the rural areas. Currency overvaluation is also related to income concentration. In this sense, it is no surprise that the recent combination of high unemployment, an overvalued currency, and low overall economic growth have resulted in greater inequality. The paper also finds that unemployment and inflation have an adverse effect on education of the poor. Thus, macroeconomic instability is detrimental for the accumulation of human capital, which in turn has a long-term effect on the distribution of income.

## 1. INTRODUCTION

This paper deals with the relationship between macroeconomic performance and equity. In line with a growing body of empirical literature, we analyze the impact of key macroeconomic variables on income distribution, as well as on the level and distribution of educational opportunities across the population. In particular, we explore the effects of economic growth, inflation, unemployment, and the degree of currency overvaluation, on several measures of income distribution. We perform similar exercises using enrollment rates (in primary, secondary, and tertiary education) as the dependent variables. The exercise is carried out both for the level of macroeconomic variables and their volatility.

The reasons why macroeconomic fluctuations are inefficient are well known. Economic theory has shown that it is optimal to smooth-out consumption across time when agents experience decreasing marginal utility. Also, macroeconomic instability results in greater uncertainty, which has a negative effect on investment. In fact, Fischer (1991) has pointed out that countries with greater macroeconomic stability experience, on average, higher economic growth. Thus, the allocation of resources is more efficient in less volatile economies.

Equity is also related to macroeconomic stability. It is often said that the poor are the chief sufferers of inflation, which is often characterized as the “cruellest tax” due to its regressive effects on income distribution. Also, the conventional wisdom views unemployment as having an inequality-augmenting effect. The argument here is that increases in unemployment have a larger impact on the earnings of the unskilled, who are the first ones to lose their jobs when aggregate employment falls. Although having intuitive appeal, the links between macroeconomic conditions and income distribution lack solid theoretical justification and have become the subject of a prolific empirical debate.

For example, using U.S. data, Blinder and Esaki (1978), and Blank and Blinder (1985) find that inflation *reduces* income concentration<sup>3</sup>. Nolan (1987) for the U.K. and Flückiger and Zarin-Nejadan (1994) for Switzerland also obtain the progressive impact of inflation. However, Blejer and Guerrero (1992) for the Philippines, and Björklund (1991) for Sweden, and Silber and Zilberfab (1994) for Israel have argued that the opposite is true. Moreover, the evidence presented by Cardoso, Paes de Barros and Urani (1995) for Brazil indicates that changes in inflation rates largely explain the sharp fluctuation of income distribution during the 1980s. In particular, they show that greater income concentration occurred during periods of higher inflation.

The effects of unemployment on income distribution are less controversial. Virtually every paper in this literature has pointed that higher rates of unemployment are

---

<sup>3</sup> Other references are Schultz (1969), Metcalf (1969), Beach (1977), Buse (1982), and Bishop, Formby and Sakano (1994).

associated with greater inequality. Indeed, building on previous work by Blinder and colleagues, Jäntti (1994) has argued that unemployment, not inflation, is the crueler tax in the U.S.<sup>4</sup> Evidence for developing countries also finds that increases in unemployment have a high social cost (see for example work by Bonelli and Ramos (1993) and Urani (1993) for Brazil).

Along a somewhat different vein, Urrutia and Cárdenas (1993) present some evidence of a strong correlation between economic fluctuations and the social cycle (i.e., deviations around trend for an array of social indicators) in four coffee producing nations (Colombia, Costa Rica, Cote d'Ivoire and Kenya). The overall conclusion of this body of literature is that macroeconomic instability is not only inefficient, but also generates unpleasant effects on equity. This is especially true in developing countries, where inflation does seem to have an unambiguous regressive effect<sup>5</sup>. However, it is important to mention that the relationship between the effects of macroeconomic instability and income distribution goes the other way. In fact, it is likely that high-income concentration can cause macroeconomic instability (see Cuckierman, Edwards and Tabellini [1991]).

This paper explores these issues using a new database on income distribution available for Colombia. In particular, based on the Household Surveys<sup>6</sup> we constructed quarterly series on income distribution and educational attainment (by income quintiles) for the period 1976:1 to 1996:2. After processing and solving the top coding problems present in the data we obtained an array of income distribution indicators (e.g. Gini and Theil coefficients, top to bottom quintile ratio, etc.) for labor and non-labor income. These indicators were computed for labor earnings by individual and for the total household income in per capita terms, arguably a better measure of individual welfare.

Using cointegration analysis, this paper concludes that there is a long-run positive relation between inflation and income concentration. A similar result is obtained in the case of unemployment. In the terminology of Engle and Granger (1991) there is an attractor that holds these variables together in the long run. Trends in income inequality are related to trends in inflation and unemployment. Error correction models indicate that the same is true for the short run fluctuations in the variables.

Other macroeconomic variables are used in the paper. The results suggest that growth in the manufacturing sector is associated with a more egalitarian urban income distribution. Also, improved economic conditions in the rural sector (agriculture and mining) reduce inequality in the cities. The argument here hinges on the influence that rural sector conditions have on unskilled labor migration to the cities. Conversely, growth in nontradable sectors (e.g., construction and services) results in greater

---

<sup>4</sup> He estimates the same equations as in Blinder and Esaki (1978) using GLS rather than OLS and finds that inflation has progressive effects and that unemployment has diminishing regressive effects.

<sup>5</sup> Recently, however, Ferreira and Litchfield (1997) using total household income per capita (rather than labor income) have found a negative correlation between unemployment and inequality for Brazil during the 1990s.

<sup>6</sup> These surveys collected data for the 4 largest metropolitan areas prior to 1982 and for 7 areas since then. The change in the sampling properties introduces some methodological problems that are dealt with later.

inequality. Lastly, a real depreciation of the currency is associated with improvements in income distribution.

The paper is divided in 5 sections. Section 2 describes the data and presents some stylized facts on income distribution and educational attainment in Colombia. Section 3 discusses some of the possible mechanisms that create a link between macroeconomic variables and social progress. Section 4 estimates a cointegrating vector that establishes a long-run relationship between income distribution and macroeconomic performance. Section 4 applies an identical procedure in order to capture the relationship between educational advancement and macroeconomic variables. Section 5 concludes.

## 2. DATA

### 2.1 INCOME DISTRIBUTION

This section presents the stylized facts on income distribution in Colombia, based on a new data set obtained from the Household Surveys. These surveys suffer from several methodological problems that had to be solved in order to construct our database. The main difficulties with the raw data are related to: i. Top-coding problems in reported incomes<sup>7</sup>; ii. Measurement errors on the part of the surveyors.

Top coding problems are present in most of the surveys. Until September 1993 the questionnaire allowed up to six digits for monthly incomes, so that higher end incomes were increasingly underestimated<sup>8</sup>. Since September 1993 seven digit incomes were allowed, but even then a fraction of the surveyed individuals reported the top coded income. This problem was finally solved in March 1996 (the surveys no longer have limits on the maximum income reported). In order to correct for truncated incomes in the survey we implemented a procedure, which is described in Appendix 1<sup>9</sup>. The procedure is relatively ad hoc, but has better statistical properties than alternative methodologies. In order to compare the results of available procedures we artificially impose top-codes on the incomes of an untruncated survey. If truncation problems are solved using a lognormal distribution the Gini coefficient is overestimated by 2.44%. In contrast, the degree of overestimation is only 0.07% when our procedure is used.

Measurement errors on the part of the surveyors refer to the fact that many workers report a weekly (or by-weekly) payment of their salary, but express their salary in monthly terms. We found that the monthly incomes of some workers had been overestimated due to the fact that a monthly salary had been (wrongly) multiplied by

---

<sup>7</sup> Cárdenas and Gutiérrez (1996) describe in detail the top-coding problems and survey the alternative solutions that have been proposed in the literature.

<sup>8</sup> At the 1993 exchange rate, the maximum allowed monthly income (Col\$999.998) was equal to US\$1,200.

<sup>9</sup> The procedure is based on the estimation of the maximum level of income for the individuals whose incomes are truncate. Once that level is estimated we then fit an exponential function to distribute the incomes of the truncated population.

the frequency of payment. We dealt with this problem by identifying outliers in groups with similar socioeconomic characteristics.

Throughout the paper we use three definitions of income. All our income concepts are based on primary sources. Thus, we ignore the role of transfers and subsidies to households<sup>10</sup>. First, we use pre-tax labor earnings for the individual. Second, we use pre-tax non-labor income (pensions, interest payments, dividends, and rents) where the receiver is also the individual. Third, we computed the gross monthly household income (from all sources). Our results are robust to the choice of income measure.

In order to describe the data we performed some static decompositions of inequality in Colombia. The goal is to separate total inequality into a component of inequality between some arbitrarily chosen groups, and the remaining within-group inequality. The individuals can be grouped according to age, gender, educational attainment, geographical location (e.g., urban vs. rural), ethnicity, etc. In the case of household income these partitions can be made according to the characteristics of the household head.

In order to perform these decompositions we use the Theil index, which is a particular case of the generalized entropy class of measures. The partition of the overall distribution by individual attribute was carried for level of education. In particular, we calculated:

$$T_T = \sum_{k=1}^k q_k \sum_{j=1}^j \frac{q_{j,k}}{q_k} \ln \frac{q_{j,k}/q_k}{p_{j,k}/p_k} + \sum_{k=1}^k q_k \ln \frac{q_k}{p_k} \quad (1)$$

where  $q_k$  is group's  $k$  share in total income (groups were defined according to the years of schooling of the population)<sup>11</sup>,  $q_{j,k}$  is the share of individual  $j$  in group  $k$ ,  $p_k$  is the share of group  $k$  in total population and  $p_{j,k}$  is the share of individual  $j$  in group  $k$ . The first term on the right hand side is the Theil index within groups ( $T_W$ ) and the second term is the Theil index between groups ( $T_B$ ). The ratio  $R_B = \frac{T_B}{T_T}$  measures the share of inequality that can be explained with the attribute that defines the groups' partition<sup>12</sup>. In our case, the within groups entropy index measures the part of inequality that cannot be explained with educational differences.

---

<sup>10</sup> Cárdenas and Vélez (1996) show that these forms of secondary income have played a decisive role on income distribution in Colombia in recent years.

<sup>11</sup> The  $k$  groups correspond to: i. 0 years, ii. 1 to 5 years, iii. 6 to 10 years, iv. 11 years, v. 12 to 15 years and vi. 16 years.

<sup>12</sup> See Cowell and Jenkins (1995) for a formal derivation of all Generalized Entropy measures.

Figure 1 shows the total and within-groups Theil indexes for labor incomes. A cursory look at the graph suggests the presence of a rapid decline in inequality between 1976 and 1982, followed by stability during the 1980s. During the 1990s inequality has increased substantially. Interestingly enough, the partition by educational attainment of the population does not seem to explain much of total inequality. In fact,  $R_b$  lies between 28 and 34% for the period 1976-1996 so the between-group component is not substantial. This is of interest because it implies that a large share of inequality can be explained with macroeconomic variables<sup>13</sup>.

Moreover, it is worth noticing that the reduction in inequality between 1976 and 1982 was mainly due to a reduction in inequality between groups, while the recent increase is the result of greater within-groups inequality. Thus, the role of macroeconomic factors is potentially larger in explaining changes in income distribution throughout the 1990s. This is of interest because it suggests that structural reforms cannot be held accountable for the higher skewness of the distributional curve. As we will argue, emphasis should rather be placed on greater macroeconomic instability in recent years.

To complete this description we use other measures of inequality, such as the Gini coefficient, and the share of income received by each quintile of the population. Figure 1 also shows the Gini coefficient for labor earnings by individual. According to the data, primary income is highly concentrated in Colombia. In fact, when comparing our measures with the evidence gathered in Deininger and Squire (1996) Colombia emerges as one of the countries with greater inequality in Latin America (already the region with greater inequality in the world). The trends are fairly close to those described before: The Gini coefficient experienced a drastic reduction from 0.49 in 1976 to 0.40 in 1982. Since 1991 it has increased to the levels observed in the late 1970s.

Figure 2 shows share of labor income by quintile, as well as the top-to-bottom quintile ratio<sup>14</sup>. These data confirm the mentioned trends: Until the early 1980s all the measures point towards a reduction in income concentration. This trend reversed during the late 1980s. According to the 1996 data, the top quintile received 54% of total income, while the bottom quintile received 6%. The 5:1 ratio indicates that the share of the top quintile is 9 times larger than that of the bottom quintile. In fact, the top quintile's share has increased steadily during the 1990s.

Figures 3 and 5 show the same variables calculated with non-labor income only. Clearly, in this case the concentration of income is much higher. In 1996, only 2.7% of non-labor income was received by the bottom decile, while 60% went to the top 20% of the population. Moreover, the Gini coefficient has increased from 0.56 in 1990 to 0.62 in 1996.

---

<sup>13</sup> This result is consistent with Núñez and Sánchez (1997) who find that approximately 28% of inequality can be explained by differences in educational attainment across the population.

<sup>14</sup> This ratio has some advantages over the Gini coefficient. See Deininger and Squire (1996).

Lastly, Figures 4 and 5 depict income distribution variables based on the total household income in per capita terms<sup>15</sup>. Since the average size of low-income households is relatively larger, income distribution is more skewed according to these measures. The top to bottom quintile ratio was 14 in 1996 (10 in 1982), a figure that is likely one of the highest in the developing world. More worrisome is the trend observed since 1991. The top quintile's share rose from 54.7% in 1991 to 57.8% in 1996.

## 2.2 EDUCATION

As shown in the previous section, educational attainment is one of the attributes that can explain total inequality. But education itself is a variable attribute (such as income) that can respond to macroeconomic conditions. Hence, causation running from education to income distribution is misleading. It is probably more accurate to treat education and income distribution as endogenously and simultaneously determined by a common set of factors which include macroeconomic conditions.

This section describes the data on education gathered from the Household Surveys. Figure 6 shows gross enrollment rates in primary, secondary and tertiary education for the bottom and top quintiles of the population. A cursory look indicates that enrollment rates have increased significantly during the 1990s. This is true for primary and secondary education for the bottom quintile and for all levels of education for the top quintile. These trends are consistent with the rapid increase in public expenditure in education, which rose from 3.0% of GDP in 1990 to 3.7% in 1995<sup>16</sup>.

Enrollment rates in secondary education show the fastest increase (48% in 1982 to 62% in 1996). This increase is more dramatic for the bottom quintile (from 35% in 1982 to 57% in 1996). Figure 7 shows the average years of schooling for the urban population calculated from the Household surveys. According to the data, the average educational attainment of the population rose from 7.5 to 9 years between 1982 and 1996. The lower part of Figure 7 displays the ratio in terms of years of schooling of the top and bottom quintiles. The data indicates that the educational gap has narrowed since 1982<sup>17</sup>. In the next section we deal with the relationship between these trends and macroeconomic performance.

---

<sup>15</sup> The sum of total income (labor and non-labor) of the household divided by the number of individuals in the household.

<sup>16</sup> According to the data in Londoño (1997).

<sup>17</sup> According to the 1993 National Census, 14% of the population over 5 years was illiterate. Nevertheless, when computing this rate again with population over 15 years, we obtain 3.5% of illiterate population. Based on the 1985 National Census the adult illiterate rate was approximately 11% while in countries with average income this rate was 25% and in Latin American countries it corresponded to 17%. In spite of this, we are yet far from developed countries' rates (approximately 5%). For a detailed analysis on illiteracy see World Bank (1991).

### 3. INCOME DISTRIBUTION AND MACROECONOMIC STABILITY

As mentioned in the introduction, the time series regressions linking macroeconomic variables and income distribution data have a long tradition in the literature<sup>18</sup>. For example, in the case of the U.S., Schultz (1969), Metcalf (1972), Thurow (1970), Blinder and Esaki (1978) use income shares (by quintile), Gini coefficient and the Theil index as the dependent variable. Unemployment is always a significant explanatory variable, whereas the effects of inflation and the factorial distribution of income are less conclusive. Indeed, Blinder and Esaki (1978) find that increases in inflation rates are associated with a more egalitarian distribution. In contrast, Metcalf (1972) finds evidence suggesting the opposite effect. The difficulty with the time series approach is that other factors that affect income distribution are difficult to isolate.

This body of literature has identified several transmission mechanisms from macroeconomic stability to income distribution<sup>19</sup>. Economic activity can have different effects on income distribution depending on the impact on the composition of output and on the compensation of the different factors of production. The conventional wisdom argues that labor market deterioration (maybe due to its depressing effects on wages) affects low income groups more adversely than high income groups. This could also result from greater flexibility in the unskilled labor market (due, for instance, to differences in the labor legislation). Although imprecise about the specific mechanism, the literature agrees that unemployment adversely affects the lower end of the income distribution.

Although the evidence for developed countries is mixed, inflation does seem to be a regressive distributive device in developing countries. Neri (1995) discusses several channels through which inflation can result in greater inequality: (i) economies of scale in financial transactions; (ii) limited access (by the poor) to indexed financial assets; (iii) higher degree of wage indexation for skilled workers (in other words, the degree of indexation increases with the level of skill); (iv) lower share of durable goods in the consumption basket of the poor. Of course, these channels are less relevant in the case of high-income and low inflation countries. Thus, the fact that inflation has a statistically significant progressive effect on the distribution of income in the U.S. and the U.K. may be due to the fact that in those economies (unexpected) inflation proxies for an increase in aggregate demand. At any rate, it is hard to identify *a priori* the effects of inflation on equity. Dealing with this issue becomes an empirical question.

Lastly, Demery and Addison (1987) have analyzed the effect of the real exchange rate on income distribution. According to their results, the effect depends on price and

---

<sup>18</sup> There are other approaches, however. Budd and Whiteman (1978) and Minarik (1979) are examples of papers based on simulation exercises. In the latter case, higher inflation reduces the value of long-term assets and implies a form of redistribution from creditors to debtors.

<sup>19</sup> See Nolan (1989), Bjorklund (1991), Blejer and Guerrero (1992).

wage flexibility, and the relative weight of traded and nontraded production for the different groups of the population.

Following that line of research, this paper estimates the following equation:

$$S_t = \alpha + \beta u_t + \gamma \pi_t + \delta e_t + \sum_i \rho_i g_{it} + \varepsilon_t \quad (2)$$

where  $S_t$  is a measure of income distribution (e.g., top-to-bottom quintile ratio, Gini coefficient, and the within groups Theil index),  $u_t$  is the unemployment rate,  $\pi_t$  is the inflation rate,  $e_t$  is the real exchange rate and  $g_{it}$  is the growth rate in sector  $i$ . Alternative versions of the model included a quadratic term on unemployment, and lags on the dependent and explanatory variables. Also, the equation can be estimated with the volatility of unemployment and inflation (measured by a rolling standard deviation) and the business cycle (measured by the deviations in output around a Hodrick-Prescott trend), instead of the macroeconomic variables in levels. The source for all the explanatory variables is DANE, except the GDP quarterly series, which come from DNP and the multilateral real exchange rate, which is obtained from the Banco de la República.

The results of estimating equation (2) are of interest. It is well known that the usual techniques of regression analysis can result in highly misleading conclusions when variables contain stochastic trends (Granger and Newbold [1974]). In particular, if the dependent variable and at least one independent variable contain stochastic trends, and if they are not cointegrated, the regression results are spurious. To identify the correct specification of the model depicted by equation (2) it is necessary to analyze the presence of stochastic trends in the variables. To this end, augmented Dickey-Fuller tests were performed on all the variables of the model (see Table A1 for the results). The statistic  $\tau_\beta$  corresponds to the model with intercept and trend, the statistic  $\tau_\mu$  to the model that contains only an intercept and, finally, the statistic  $\tau$  indicates the model was estimated without both intercept and trend. The values tabulated by McKinnon (1991) are used given that the estimated coefficients do not have the usual asymptotic distribution. As shown in Table A1, the null hypothesis of the existence of a unit root cannot be rejected for any of the variables<sup>20</sup>.

Additionally we used the Hylleberg-Engle-Granger-Yoo (HEGY) test for quarterly data in order to test for seasonal unit roots. The results are reported in Table A2 and indicate that almost all the variables show a unit root at zero frequency ( $\pi_1$ ), but not in the half yearly frequency ( $\pi_2$ ) nor the annual frequency ( $\pi_3$  y  $\pi_4$ ). Only primary enrollment rates show a unit root in the half yearly frequency<sup>21</sup>.

<sup>20</sup> Appendix 3 presents Perron's test for unit root in the presence of structural changes for some of the variables, nevertheless, as magnitudes of these changes are pretty small, only Dickey-Fuller and HEGY tests were used to decide about the stationarity of variables.

<sup>21</sup> For this reason, these variables were de-seasonalized using the X11 procedure.

Given that all variables in equation (2) are I(1) we used the Johansen cointegration test<sup>22</sup>. In order to capture the long and short run relationships between the variables we also estimated the corresponding vector error correction model (VEC). These techniques diminish the risks of obtaining spurious results, which are likely to be pervasive in the previous literature.

Table A3 shows the results of the cointegration test using the income distribution variables<sup>23</sup>. They indicate that all groups of variables are cointegrated, which implies that a long run relationship between the variables holds. Three of the systems shown have two cointegrating vectors, while the last system has three vectors at the 5% confidence. Table 1 shows the cointegrating vector (normalized for the income distribution variable) that corresponds to the theoretically expected results.

According to the results presented in Table 1, the unemployment rate has a regressive and significant effect on income distribution. Higher rates of unemployment are associated with increases in the top-to-bottom quintile ratio (as well as in the Gini coefficient) computed either with labor income or with the total household income in per capita terms. This result implies that unemployment causes a significant social cost, probably due to the fact that unskilled workers are more likely to lose their jobs once a drop in employment starts. The error correction model results (not shown) indicate that all income distribution variables used significantly respond to past deviations from the long run equilibrium of the variables in the system. Nevertheless, these temporary deviations take a long time to be corrected. The coefficient indicates that, on average for the entire sample, only 8% of the short run disequilibrium between the income distribution variable and the other variables included in the system is corrected within one quarter.

Figures 8 and 9 show the impulse-response exercise for the systems in Table 1 using total household income per capita. These graphs are based on the error correction model where the short run dynamics between the variables of the system are influenced by the long run deviation from equilibrium. We show the response of the top to bottom quintile ratio and Gini coefficient to a one standard deviation in each of the macroeconomic variables. As can be seen, a one standard deviation shock in the unemployment rate causes an increase in income concentration, indicating that unemployment has a regressive impact on the distribution of income. Moreover, the effect tends to be of permanent nature.

---

<sup>22</sup> There are three main reasons for this choice: First, Gonzalo (1994) shows that the Johansen test performs better than other approaches under various specifications errors. Second, Johansen's approach is able to incorporate cointegration into the familiar VAR representation without restrictions on the exogeneity of the variables. Third, the procedure provides simultaneously test statistics to infer the number of cointegrating relationships and estimates of the cointegration vectors.

<sup>23</sup> All systems used in this exercise include a dummy variable that equals 1 in the second quarter of 1982, due to the fact that the sample was changed from 4 to 7 metropolitan areas, and in each city the number of interviewed individuals increased from 10.000 to approximately 30.000.

On the other hand, the results in Table 1 indicate that inflation has a regressive and significant effect on the distribution of income. Higher inflation rates lead to increasing levels of inequality, as measured by the top-to-bottom quintile ratio and the Gini coefficient (computed with labor earnings and total household income per capita). The impulse-response analysis indicates that a one standard deviation shock in the inflation rate increases the top-to-bottom quintile ratio (based on total household income per capita). In the case of the Gini coefficient based on total household income the effect is positive but practically zero after two years (see Figure 9)<sup>24</sup>. In sum, the evidence suggests that the inflation tax is regressive in Colombia, possibly due to the fact that the earnings of the poor are less indexed than for other income groups. Also, groups at the higher end of the income distribution scale can protect themselves against inflation acquiring real assets, a possibility that is less feasible for the poor.

From the results reported in Table 1 it can also be inferred that once we control by the unemployment rate, the growth in manufacturing has a significant progressive effect. This result can be attributed to the intensive use of unskilled labor in the manufacturing sector. In fact, according to the Annual Manufacturing Survey conducted by DANE, the share of unskilled labor in total manufacturing employment was 75% in 1976 and 65% in 1994. Moreover, the manufacturing sector represented approximately 23 to 30% of the urban GDP between 1976 and 1996.

After analyzing the impulse-response exercise shown in Figures 8 and 9 we can see that a standard deviation shock in the growth in manufacturing causes a reduction in the measures of income concentration. The effect is progressive during the first 4 quarters after the shock but practically zero thereafter.

Additionally, the cointegration exercise allows us to infer that growth in agriculture and mining has a significantly progressive effect. Interestingly, this result suggests that favorable conditions in the rural sector reduce unskilled migration to the cities, thus reducing the possibility of significant urban income concentration. The short run analysis presented in the impulse-response exercises clearly shows that a standard deviation shock in the growth in agriculture and mining permanently reduces all measures of income concentration.

In contrast, after controlling for the effect of unemployment, growth in urban non-tradable activities raises income concentration. In fact, the estimated coefficient indicates that an increase in the growth in nontradables raises the top-to-bottom quintile ratio and the Gini coefficient. This result is difficult to interpret, but could be suggestive of a higher degree of capital and skilled labor intensity in those sectors. The impulse-response analysis shows that one standard deviation increase in the growth in nontradable sectors is associated with an increase of all income concentration measures.

---

<sup>24</sup> It is important to remember that an increase in the Gini coefficient is not relation exclusively to transfers from the bottom to top quintiles. In fact, this can also happen if transfers from the second to fourth quintile, or third to fourth quintile take place.

Finally, the results presented in Table 1 indicate a clearly progressive effect of a real depreciation of the currency<sup>25</sup>. This result can be due to the fact that a considerable proportion of Colombian exports is intensive in unskilled labor. Thus, the loss induced by the increase in the price of tradable goods is less than the gain due to the increase in real earnings. The impulse-response analysis indicates a negative (progressive) impact of a standard deviation shock in the real exchange rate. Nevertheless, this effect is small in terms of magnitudes. In fact, for the case of the top to bottom quintile ratio and Gini coefficient computed with total household income, the effect of a shock in the real exchange rates is nearly zero after a year from the initial impact.

Table 2 estimates the same cointegrating equation using the income share by each quintile as a measure of income concentration. The results are of interest because they suggest that, in relation to macroeconomic performance, the behavior of the share of the top quintile is remarkable different than for the remaining quintiles. In fact, inflation and unemployment increase the income share of the top quintile, while the opposite happens to the share of the remaining 80% of the population.

Table A3 also shows a similar cointegration exercise that includes growth separated in two components: the part of growth due to the increase in employment and the part of growth due to changes in multifactorial productivity. For that purpose we calculated the quarterly Solow residual<sup>26</sup> for urban output, based on GDP data from the National Planning Department (DNP), employment data from the National Household Survey and a quarterly capital stock based on the investment information estimated by the DNP. According to the calculation, total factor productivity has increased significantly since 1992.

The results shown in Table 3 indicate that growth in urban employment reduces the degree of income concentration. However, growth in multifactorial productivity has the opposite effect on income distribution. This is an uncomfortable result, suggesting that gains in efficiency are not immediately transferred to the poor. Increases in productivity in our basic calculation can be derived from improvements in education, technology or infrastructure. Thus, the result is not surprising if the individuals at the higher end of the distribution of income are also the ones with greater access to those assets.

---

<sup>25</sup> This result coincides with Blejer and Guerrero (1992) for the Philippine case.

<sup>26</sup> Using a Cobb-Douglas technology. The parameters of the production function were estimated econometrically. The share of employment in total product is approximately 0.6 and the share of capital is 0.4.

#### 4. HUMAN CAPITAL AND MACROECONOMIC STABILITY

In this section, we estimate equation (2) but use measures of educational attainment rather (than income distribution) in the left-hand-side. Specifically we use enrollment rates in primary, secondary, and university education as the dependent variables. The main objective is to assess the impact of macroeconomic performance on education. We look at the effects of macroeconomic variables on the educational attainment of the different quintiles of the population. We argue that macro conditions have an effect on the distribution of human capital, which as we saw is significant determinant of income distribution. Thus, the effect of macroeconomic fluctuations on equity goes beyond their direct impact on income. Macroeconomic conditions also have an impact on the distribution of assets.

Table A4 shows the Johansen cointegration test for each of the systems that include enrollment rates and the above-mentioned macroeconomic variables. In all cases, the existence of two cointegrating vectors at 5% confidence is found, except for university coverage in the top quintile, which exhibits only one cointegrating vector. These results suggest the presence of a long run relationship between educational attainment and macroeconomic performance in Colombia. Although not reported, the same results are obtained when enrollment rates for the entire population in the Household surveys are used.

Table 4 presents the normalized cointegrating vectors. Unemployment has a negative (and in most cases significant) effect on the enrollment rates for all levels of education, except university in the top quintile. This can be linked to the fact that deteriorating conditions in the labor market motivate adult participants of the labor market to retire temporarily, finding in university an alternative activity.

The results also indicate that higher inflation is related to a reduction in enrollment rates for all levels of education. This is true both for the bottom and top quintiles of the population. However, when the exercise is carried out for the entire population the effect is only significant in the case of enrollment rates in university education. Manufacturing output growth (a proxy of urban economic conditions) raises enrollment rates in primary and secondary education, but diminishes enrollment at the university level. Improved economic conditions seem to attract individuals into the labor force and out of university.

The effects of the real exchange rate on education are somewhat puzzling. A more depreciated currency seems to have a negative impact on enrollment in primary and secondary education, and a positive effect on university enrollment rates.

Finally, and as expected, the average years of schooling in the corresponding quintile are positively (and significantly) related to the enrollment rates. This result

clearly confirms the existence of a virtuous cycle between education of a group and the motivation to create more education within it<sup>27</sup>. The educational attainment of the household head is a good predictor of the enrollment rates in all educational categories.

Figure 10 depicts the results of the impulse-response exercise using enrollment rates for the entire population as the variable of interest<sup>28</sup>. A one-standard deviation increase in the unemployment rate has a negative effect on primary and secondary education enrollment rates. The graphs also show that positive shocks to inflation are detrimental from the point of view of enrollment in primary education. It is important to mention that according to the error correction model (not shown) all enrollment rates respond significantly to past deviations from the long run equilibrium between the variables of the system. In fact, any temporary deviation takes a short time in being corrected: between 80 and 90% of the short run discrepancy is corrected within a quarter.

---

<sup>27</sup> These results coincide with the conclusions in Sánchez and Núñez (1996).

<sup>28</sup> Impulse-response functions for secondary and university enrollment rates are available upon request.

## 5. CONCLUSIONS

Colombia stands out as one of the countries with greater inequality in Latin America. Moreover, throughout the 1990s the country has experienced a significant increase in income concentration. The standard explanation links these trends to the effects of structural reform, especially trade liberalization. This paper adopts an alternative approach and explores the relationship between macroeconomic conditions and urban income distribution in Colombia. This is of interest because variables that explain differences in income between groups, such as education, cannot account for recent changes in inequality. In fact, a standard decomposition exercise indicates that increased income concentration is largely due to greater within-group inequality.

The results show that unemployment and inflation have significant regressive effects on the distribution of income. After controlling for these variables, economic growth seems to have disparate effect on equity. Manufacturing output growth is clearly progressive, possibly due to its effect on unskilled employment. Improved conditions in the rural areas (measured by growth in agriculture and mining) deter unskilled labor migration to urban areas, reducing income concentration in the cities. A more depreciated currency also seems to have a progressive effect, due to the intensive use of unskilled labor in Colombian exports. Growth in nontraded goods production has an adverse effect from the point of view of income distribution. In this sense, it is no surprise that the recent combination of high unemployment, a strong currency, and low growth in agriculture and manufacturing have resulted in greater inequality.

The paper also finds that unemployment and inflation have an adverse effect on education of the poor. Thus, macroeconomic instability is detrimental for the accumulation of human capital, which in turn has a long-term effect on the distribution of income.

**APPENDIX 1**  
**HOUSEHOLD SURVEYS: METHODOLOGICAL ISSUES**<sup>29</sup>

Top-coding problems were registered between September 1982 and December 1995 (stages 36 through 90), when limits on the maximum reported monthly income were imposed (6 digits until June 1993 and 7 digits between September 1993 and December 1995). We corrected this problem by estimating the maximum income for the truncated surveys for each occupational category (employee, employer, and self-employed). Figure A1 shows the employers' income (in logs) for the surveys of September 1983 (top, truncated) and September 1982 (bottom, untruncated). In the top curve, the incomes of X individuals were truncated.

In order to estimate the maximum income for this group, we calculated the average annual growth rate in the incomes of a group of high-income individuals of identical size as X, but whose incomes had not been truncated. We applied this growth rate to the maximum income reported in the untruncated survey. This gives point P in

the Figure.

**Figure A1**

Once that maximum income (P) was calculated we fitted an exponential function between points O and P. The estimated income of the X (truncated) individuals are given by:

<sup>29</sup> We would like Jaime Alberto Jiménez for his assistance in the elaboration of this Appendix.

$$Y_i = e^{\alpha n_i - \beta} + vc + \chi n_i \quad (A1)$$

where  $\beta = \alpha n - \ln(vm - vc - \chi n)$ ,  $\alpha$  and  $\chi$  are parameters of the exponential function,  $vc$  is the truncation value (Col\$999,998 between stages 37 and 80, and Col\$9'999,998 between stages 81 and 90),  $vm$  is the maximum (estimated) income in the truncated survey, and  $n$  is the number of individuals with truncated incomes. In order to obtain the parameters of the exponential function we estimated equation A1, with  $vc$  equal to income at point N,  $vm$  is income at point O (truncation value), and let  $\alpha$  iterate between 0 and 4 and  $\chi$  between 0 and 200,000. We chose the parameters that minimized the errors of the fit *vis à vis* the original data.

In Figure A1 we compare our results with those obtained with a lognormal distribution. For that purpose we artificially truncate an untruncated survey. The lognormal distribution overestimates the average income by 9.5% and the Gini coefficient by 2.44%. Our methodology overestimated income by 0.9% and the Gini coefficient by 0.07% only.
